Proposed interface for Standard ML Stream I/O

Andrew W. Appel

February 6, 1995

1 Introduction

The Input/Output interface provides:

- buffered reading and writing;
- arbitrary lookahead, using an underlying “lazy streams” mechanism;
- dynamic redirection of input or output;
- random access;
- uniform interface to text and binary data;
- layering of stream translations, through an underlying “reader/writer” interface;
- unbuffered input/output, through the reader/writer interface or even through the buffered stream interface;
- primitives sufficient to construct facilities for random access reading/writing to the same file.

In addition, the prescriptions and recommendations herein allow for efficient implementation, minimizing system calls and memory-memory copying.

The I/O system has several layers of interface. From bottom to top, they are

PRIM.IO Uniform interface for unbuffered reading and writing at the “system call” level, though not necessarily via actual system calls.

STREAM.IO Buffered “lazy functional stream” input; buffered conventional output.

IO Buffered, conventional (side-effecting) input and output with redirection facility.

Because most programmers will use the IO interface, I will describe that first, rather informally. Then I will go bottom-up over the entire system, giving a technical specification of the interfaces, and their axioms and pragmatics.

2 IO

Conventional buffered input/output is done using several structures matching the IO signature: TextIO, for character input/output, BinIO, for binary (byte) input/output.

signature IO =
  sig
  type instream
  type outstream
  type elem
  type vector

type pos
val closeIn : instream -> unit
val input : instream -> vector
val inputAll : instream -> vector
val inputNoBlock : instream -> vector option
val input1 : instream -> elem option
val inputN : instream * int -> vector
val endOfStream : instream -> bool
val lookahead : instream -> elem option
val setPosIn : instream * pos -> unit
val getPosIn : instream -> pos
val endPosIn : instream -> pos
val closeOut : outstream -> unit
val output : (outstream * vector) -> unit
val output1 : outstream * elem -> unit
val flushOut : outstream -> unit
val getPosOut : outstream -> pos
val endPosOut : outstream -> pos
val setPosOut : outstream * pos -> unit
structure StreamIO : STREAM IO
sharing type elem = StreamIO.elem
sharing type vector = StreamIO.vector
sharing type pos = StreamIO.pos
val mkInstream : StreamIO.instream -> instream
val getInstream : instream -> StreamIO.instream
val setInstream : instream * StreamIO.instream -> unit
val mkOutstream : StreamIO.outstream -> outstream
val getOutstream : outstream -> StreamIO.outstream
val setOutstream : outstream * StreamIO.outstream -> unit
end

structure FilePosInt : INTEGER

signature STANDARD_IO =
sig
  include IO
  sharing type pos=FilePosInt.int
  val openIn : string -> instream
  val openOut: string -> outstream
  val openAppend: string -> outstream
  val stdin : instream
  val stdout: outstream
  val stderr: outstream
end

signature BIN_IO =
sig
  include STANDARD_IO
  sharing type StreamIO.elem=Word8.word
  sharing type StreamIO.vector=Word8Vector.vector
end

signature TEXT_IO =
sig
  include STANDARD_IO
  sharing type StreamIO.elem = char
sharing type StreamIO.vector = string
structure BinIO : BIN_IO
  val inputLine : instream -> string
val translateIn: BinIO.StreamIO.PrimIO.reader -> StreamIO.PrimIO.reader
val translateOut: BinIO.StreamIO.PrimIO.writer -> StreamIO.PrimIO.writer
end

structure BinIO : BIN_IO
structure TextIO : TEXT_IO

These operations may raise the General.Io exception:

exception Io of {name: string, function: string, cause: exn}

Operations on instreams

elem
A single element (member of a stream); for TextIO streams this is char; for BinIO this is Word8.word.

vector
A sequence of elements (such as string or Word8Vector.vector).

\[ f = \text{openIn}(s) \]
Opens a file named \( s \) as a stream \( f \).

\[ \text{closeIn}(f) \]
Close \( f \); no further operations are permitted on \( f \) (they will raise the Io exception).

\[ v = \text{input}(f) \]
Read some elements of \( f \), returning a vector \( v \). If (and only if) \( f \) is at end of file, \( \text{size}(v) = 0 \). May block (not return until data is available in the external world).

\[ v = \text{inputAll}(f) \]
Return the vector \( v \) of all the elements of \( f \) up to end of stream.

\[ \text{inputNoBlock}(f) \]
If any elements of \( f \) can be read without blocking, return at least one of them. If it is possible to determine without blocking that \( f \) is at end of stream, return SOME(\text{empty}). Otherwise return NONE.

\[ c = \text{input1}(f) \]
If at least one element \( e \) of \( f \) is available, return SOME(\( e \)). If \( f \) is at end of file, return NONE. Otherwise block until one of those conditions occurs.

\[ v = \text{inputN}(f, n) \]
If at least \( n \) elements remain before end of stream, return the first \( n \) elements. Otherwise, return the (possibly empty) sequence of elements remaining before end of stream. Blocks if necessary. (This was the behavior of the input function in the 1989 Definition of Standard ML, and pre-1.00 releases of SML/NJ.)

\[ \text{endOfStream}(f) \]
False if any elements are available in \( f \); true if \( f \) is at end of stream. Otherwise blocks until one of these conditions occurs.
c = lookahead(f)
Return the next element without advancing the stream; or at end of file return NONE. Multiple-
character lookahead can be accomplished with the lazy functional stream interface; see section 5.

setPosIn(f, i)
Seek to position i in f. Not always supported (raises Io if not supported on f).

i = getPosition(f)
Tell the current position of f. Positions may not correspond 1–1 to elements in the file, but should
increase semimonotonically. Not always supported (raises Io if not supported on f).

i = endPosIn(f)
Tell the ending position of f. Not always supported (raises Io if not supported on f).

Operations on outstreams

closeOut(f)
Flush f’s buffer and close the stream (releasing operating-system resources associated with it).

output(f, v)
Write the sequence v to f.

output1(f, x)
Write the element x to f.

flushOut(f)
Flush f’s buffer: that is, make the underlying file reflect any previous output operations.

i = getPosOut(f)
Tell the current position of f  (not always supported, may raise exception). Positions may not correspond
1–1 to elements in the file, but should increase semimonotonically.

i = endPosOut(f)
Tell the ending position of f. Not always supported (raises Io if not supported on f).

setPosOut(f, i)
Seek to position i of f (not always supported, may raise exception).

Any of these functions may raise the Io exception if an operation fails (including closeOut if a buffer
cannot be flushed).

Random access

In order to avoid unnecessary limitations on file sizes, the getPos, endPos, setPos functions all operate on special FilePosInt integers:

structure FilePosInt: INTEGER

FilePosInt is abstract and does not share with Int. Int or with any other integer type.

Users can operate on the pos type using FilePosInt.+ and FilePosInt.-; or (at the risk of being
unable to process large files) convert to/from ordinary integers using FilePosInt.toDefault and File-
PosInt.fromDefault.

1 On a pipe or other interactive stream, setPosIn will often succeed if “within the buffer” but fail for larger distances. It’s
difficult for users to write a predicate that tests a stream to see whether random access is supported on the underlying device.
In John Reppy’s opinion, this is a bug. I’ve done it this way because otherwise an extra fstat system call would be needed on
every file, to see whether it supports random access.
STANDARD IO

The IO signature describes operating-system-independent input and output streams. Implementations may provide many ways of creating instreams and outstreams, using network connections, special devices, ML functions that generate or consume elements on the fly, and so on.

But in many contexts a standard way of opening files (named by simple strings)—and standard input, output, and error streams—will suffice. The STANDARD IO signature includes IO, plus:

\[ f = \text{openIn}(s) \]
Open the file named \( s \) for reading.

\[ f = \text{openOut}(s) \]
Open the file named \( s \) for writing at the beginning, truncating it if it already exists, creating it if not.

\[ f = \text{openAppend}(s) \]
Open the file named \( s \) for writing \textit{at the end}, creating it if it does not already exist. On Unix and other operating systems that support “atomic append mode,” each individual \texttt{flushOut} operation (or other output operation that flushes the buffer) appends atomically to the current end of file, even if other processes are appending to the same file between \texttt{flushOut} operations. The \texttt{openAppend} function opens a file in this mode, if possible.

\texttt{stdIn}
The standard input stream.\(^2\)

\texttt{stdOut}
The standard output stream.

\texttt{stdErr}
The standard stream for writing error messages.

Both TextIO and BinIO have \texttt{stdIn} streams \textit{(of different types)}, but these are implemented on the same underlying file. Users who do buffered input on both TextIO.\texttt{stdIn} and BinIO.\texttt{stdIn} will see arbitrary interleaving.\(^3\) The treatment of \texttt{stdOut} and \texttt{stdErr} is analogous.

TEXT IO

Text streams (TextIO.instream) contain lines of text and control characters. Text lines are terminated with \#"\n" characters.

On operating systems that use CR-LF or CR as line terminators, these will be translated to single \#"\n" characters. The inverse translation will be done on output.

More substantial translation will be done on operating systems that use, for example, escape-coded Unicode text files.

The TextIO structure provides, in addition to STANDARD IO,

\[ s = \text{inputLine}(f) \]
Read one line from a text file, returning characters up to and including the next newline character. If end-of-file is reached before a newline character, all characters remaining in the file are returned. Thus, if end-of-file is reached immediately, the empty string will result.

\[ f = \text{translateIn}(g) \]
The default (operating-system specific) translation from binary instreams to text instreams.

\[ f = \text{translateOut}(g) \]
The default (operating-system specific) translation from binary outstreams to text outstreams.

---

\(^2\)Reppy prefers the spelling \texttt{stdin}, but \texttt{stdIn} is more consistent with \texttt{openIn}, setPosIn, etc.

\(^3\)Reppy prefers that \texttt{stdIn}, \texttt{stdOut}, \texttt{stdErr} be present only in the TextIO module, not in BinIO, with an alternate method to access the standard input and output file descriptors as buffered binary streams.
Closing files on program exit

All streams created by TextIO.openIn, TextIO.openOut, BinIO.openIn, and BinIO.openOut will be closed (the outstreams among them flushed) when the ML program exits. The outstreams stdOut and stdErr will be flushed, but not closed, on program exit.

Redirecting IO streams

There is also a set of primitives to relate IO streams to the “lazy functional streams” model of input/output; and thus to the underlying unbuffered reader/writer primitives:

StreamIO

The particular instantiation of the STREAM_IO interface underlying this IO module (i.e., streams of bytes, chars, or some other element type).

\( f = \text{mkInstream}(s) \)

Create a conventional stream \( f \) from a functional stream \( s \).

\( s = \text{getInstream}(f) \)

Extract the functional stream \( s \) from \( f \). This allows arbitrary lookahead; for example:

\[
\text{fun lookaheadN}(f,n) = \\
\quad \text{let val } f' = \text{mkInstream(getInstream(f))} \\
\quad \quad \text{in inputN}(f',n) \\
\quad \text{end}
\]

This makes a “copy” \( f' \) of the stream \( f \); then \text{input} operations in \( f' \) won’t affect \( f \) (though \text{setPosIn} on \( f' \) may effectively close \( f \)). For more details, see sections 3, 4, 5, 6, and 7, which give a more precise specification of stream behavior.

\( \text{setInstream}(f,s) \)

Redirect \( f \), so that further input comes from \( s \). For example:

\[
\text{fun fromFile}(g,\text{name}) = \\
\quad \text{let val } f = \text{openIn name} \\
\quad \quad \text{val saveStdIn = getInstream stdIn} \\
\quad \quad \text{in setInstream(stdIn, getInstream f);} \\
\quad \quad g(); \\
\quad \quad \text{setInstream(stdIn, saveStdIn)} \\
\quad \text{end}
\]

For more details, see the next few sections.

\( f = \text{mkOutstream}(s) \)

Create a conventional outstream \( f \) from a StreamIO.outstream \( s \). The output streams in StreamIO are not “functional,” they are conventional streams operated on by side-effecting output. The difference between an IO.outstream and a StreamIO.outstream is that the former may be redirected using setOutstream. Think of the former as a ref of the latter.

\( s = \text{getOutstream}(f) \)

Extract the underlying outstream \( s \) from the redirectable outstream \( f \). Unfortunately, \( s \) is not “pure functional,” so there’s no equivalent of the lookahead trick shown above. Unlike instreams, if

\[
\text{val } f' = \text{mkOutstream(getOutstream } f)
\]

then operations on \( f' \) are equivalent to operations on \( f \).
setOutstream(f, s)
Useful for redirecting output. For example,

```ml
fun toFile(g, name) =
  let val f = TextIO.openOut name
  val saveStdOut = getOutstream stdOut
  in setOutstream(stdOut, getOutstream f);
    g();
  setOutstream(stdOut, saveStdOut)
  end
```

In can be argued that this is not very elegant; the function g, instead of writing stuff to stdout, should have been parameterized (in the usual ML way) on an `outstream` from the very beginning. Then the `get` and `set` primitives wouldn't be needed.

Translation
In some environments, the external representation of a text file is different from its internal representation: for example, in MS-DOS, text files on disk contain CR-LF, and in memory contain only LF at the end of each line. Binary streams (BinIO.instream) match the external files byte for byte; text streams (TextIO.instream) are translated. Normally, users of TextIO will not need to know or care about this translation; but for more sophisticated users, the translation functions are made visible as TextIO.translateIn and TextIO.translateOut. On Unix systems, these will be identity functions. See section 8.4.

3 PRIM_IO

Primitive I/O is meant to be an abstraction of the system call operations commonly available on file descriptors.

For basic "operating system" functions such as reading and writing, the input/output modules do not reference the OS structure directly. Instead, each stream is built on a PrimIO.reader or PrimIO.writer; the readers and writers contain functions that can accomplish the system calls. But it is also possible for users to synthesize readers or writers that don't do system calls at all, or do unconventional ones.

signature PRIM_IO =
sig
  type elem
  type vector
  type array
  type pos
  val posLess : pos * pos -> bool
val
datatype reader = Rd of
  {readBlock : (int -> vector) option,
   readABlock : ({data: array, first: int, nelems: int} -> int) option,
   readNoBlock : (int -> vector option) option,
   readANoBlock: ({data: array, first: int, nelems: int} -> int option) option,
   block : (unit -> unit) option,
   canInput : (unit -> bool) option,
   name : string,
   chunkSize : int,
   close : unit -> unit,
   getPos : unit -> pos,
findPos : {data: vector, first: int, nelems: int}*pos -> pos,
setPos : (pos -> unit),
endPos : (unit -> pos)
}
datatype writer = Wr of
{writeNoBlock/: (/{data/: vector, first/: int, nelems/: int/} /-/> int option/) option,
writeaNoBlock/: (/{data/: array, first/: int, nelems/: int/} /-/> int option/) option,
writeBlock/: (/{data/: vector, first/: int, nelems/: int/} /-/> int/) option,
writeaBlock/: (/{data/: array, first/: int, nelems/: int/} /-/> int/) option,
block: (unit/-/>unit/) option,
canOutput/: (unit/-/>bool/) option,
name/: string,
chunkSize/: int,
close/: unit /-/> unit/,
getPos : (unit/-/>pos/),
setPos : (pos->unit),
endPos : (unit/-/>pos/)}
val augmentIn : reader /-/> reader
val augmentOut/: writer /-/> writer
end

A file (device, etc.) is a sequence of "elements" (elem), which may (for example) be characters or bytes. The distinction between characters and bytes is necessary on DOS, where CR-LF is translated to LF when reading character files; or on Windows-NT where characters are 16-bits (Unicode) and bytes are 8 bits.

One typically reads or writes a sequence of elements in one system call: this sequence is the vector type. Sometimes it is useful to write the sequence from a mutable array instead of from the vector.

A reader is a file (device, etc.) opened for reading, and a writer one opened for writing.

The components of a reader are

`close()`
Closes the reader (for example, frees operating system resources). Further operations to this reader are illegal and must be checked for by the reader (the General.ClosedStream exception must be raised).

`name`
The name associated with this file or device, for use in error messages shown to the user.

`chunkSize`
The recommended (efficient) size of read operations on this reader. This is typically to the block size of the operating system's buffers. If that is not known, a value of 2048 or 4096 will probably work well. ChunkSize = 1 strongly recommends (but cannot guarantee, since buffering occurs in other modules, not this one) unbuffered I/O on this reader. ChunkSize = 0 is illegal.

`readNoBlock(n)`
(optional) Reads i elements without blocking, for 1 < i ≤ n, creating a vector v, returning SOME(v); or (if end of file is detected without blocking), returns SOME(empty); or (if a read would block) returns NONE.

`readBlock(n)`
(optional) Reads i elements for 1 < i ≤ n returning a vector v of length i; or (if end of file is detected) returns an empty vector. Blocks (waits) if necessary until end of file is detected or at least one element is available.
readaNoBlock(buf=a,first=i,nelems=n)
  (optional) Reads $k$ elements without blocking, for $1 < k \leq n$ into $a_i, \ldots, a_{i+k-1}$, returning $\text{SOME}(k)$; if no elements remain before end-of-file, returns $\text{SOME}(0)$ without blocking; or (if a read would block) returns $\text{NONE}$.

readaBlock(buf=a,first=i,nelems=n)
  (optional) Reads $k$ elements for $1 < k \leq n$ into $a_i, \ldots, a_{i+k-1}$, returning a vector $k$; blocks (waits) if necessary until at least one element is available. If no elements remain before end-of-file, returns $0$.

block()
  (optional) Returns only when at least one element is available for read without blocking.

canInput()
  (optional) Returns true iff the next read can proceed without blocking.

$p = \text{getPos}()$
  Tells the current position in the file. Useful even for non-seekable files, especially if the $\text{endPos}$ function is provided (because large input operations are more efficient if the distance from "here to end of file" is known).

  The $\text{getPos}$ function must be nondecreasing (in the absence of $\text{setPos}$ operations, or other interference to the underlying object). Where $\text{setPos}$ is not provided, the reader can just count the elements returned from read operations and $\text{getPos}$ can tell the count. But an implementation of $\text{getPos}$ that always returns zero is legal.

$p' = \text{findPos}((\text{data}=v, \text{first}=i, \text{nelems}=n), p)$
  Tells the position $p'$ of the $(i+n)$th element of the vector $v$, assuming that the position of the $i$th element is $p$. Section 8.4 explains why this is useful.

$\text{setPos}(i)$
  (optional) Move to position $i$ in file. Optional, in the sense that it may raise an exception if unimplemented or invalid.

$\text{endPos}()$
  The position at the end of the file. Optional, in the sense that it may raise an exception if unimplemented, or invalid on this reader.

Providing more of the optional functions increases functionality and/or efficiency of clients:

1. Absence of all of $\text{readBlock}$, $\text{readaBlock}$, and $\text{block}$ means that blocking input is not possible.

2. Absence of all of $\text{readNoBlock}$, $\text{readaNoBlock}$, and $\text{canInput}$ means that non-blocking input is not possible.

3. Absence of $\text{readNoBlock}$ means that non-blocking input requires two system calls (using $\text{canInput}$, $\text{readBlock}$).

4. Absence of $\text{readaNoBlock}$ or $\text{readaBlock}$ means that input into an array requires extra copying. But the "lazy functional stream" model does not use arrays at all.

The $\text{augmentIn}$ function takes a reader $r$ and produces a reader in which as many as possible of $\text{readBlock}$, $\text{readaBlock}$, $\text{readNoBlock}$, $\text{readaNoBlock}$ are provided, by synthesizing these from the operations of $r$. For example, $\text{augmentIn}$ can synthesize $\text{readBlock}$ from $\text{readNoBlock} + \text{block}$, synthesize vector reads from array reads, synthesize array reads from vector reads, as needed.

If the reader can provide more than the minimum set in a way that is more efficient than the obvious synthesis than by all means it should do so. Providing more than the minimum by just doing the obvious synthesis inside the PrimIO layer is not recommended because then clients won't get the "hint" about which are the efficient ("recommended") operations.
5. Absence of `endPos` means that very large inputs (where vectors must be pre-allocated) cannot be done efficiently (in one system call, without copying).

6. The client is likely to call `getPos` on every read operation. Thus, the reader should maintain its own count of (untranslated) elements to avoid repeated system calls. This should not be done on streams opened for atomic append, of course, where the information cannot be obtained except by a system call.

7. Absence of `setPos` prevents random access.

8. The `findPos` function is needed in conjunction with readers that do translation, so that positions do not always correspond 1-1 to elements returned from `read`. If the translation function is invertible, then `findPos` will be straightforward to implement. If not invertible, then `findPos` can seek to `pos` in the underlying file, and re-translate forward to the right point. In that case, the implementation of `findPos` will probably require: \( p_0 = \text{get}() \), `setPos(pos)`, `read`, `setPos(p_0)` to restore the file position to what it was before the `find` operation.

9. Readers that do no translation, so that positions do correspond 1-1 to elements returned from the `read` functions, can provide a very simple `findPos` function:

   ```
   fun find({data, first, nelems}, p) =
   FilePosInt.*(p, FilePosInt.fromDefault nelems)
   ```

10. Readers whose `getPos` always returns zero should also have a `findPos` that always returns zero.

The components of a `writer` are:

- `writeBlock{buf=v, first=i, nelems=n}`
  This (optional) function writes elements \( v_i, \ldots, v_{i+k-1} \), for \( 0 < k \leq n \) to the output device, and returns \( k \). If necessary, waits (blocks) until the external world can accept at least one element.

- `writeaBlock{buf=a, first=i, nelems=n}`
  This (optional) function writes elements \( a_i, \ldots, a_{i+k-1} \), for \( 0 < k \leq n \) to the output device, and returns \( k \). If necessary, waits (blocks) until the external world can accept at least one element.

- `writeNoBlock{buf=v, first=i, nelems=n}`
  This (optional) function writes elements \( v_i, \ldots, v_{i+k-1} \), for \( 0 < k \leq n \) to the output device without blocking, and returns `SOME(k)`; or (if the write would block) returns `NONE`.

- `writeaNoBlock{buf=a, first=i, nelems=n}`
  This (optional) function writes elements \( a_i, \ldots, a_{i+k-1} \), for \( 0 < k \leq n \) to the output device without blocking, and returns `SOME(k)`; or (if the write would block) returns `NONE`.

- `block()`
  This (optional) function does not return until the writer is guaranteed to be able to write without blocking.

- `canOutput()`
  (optional) Returns `true` iff the next write can proceed without blocking.

- `name`
  The name associated with this file or device, for use in error messages shown to the user.

- `chunkSize`
  The recommended (efficient) size of write operations on this writer. This is typically to the block size of the operating system's buffers. If that is not known, a value of 2048 or 4096 will probably work well. `ChunkSize = 1` strongly recommends (but cannot guarantee, since buffering occurs in other modules, not this one) unbuffered I/O on the writer. `ChunkSize <= 0` is illegal (functions in other modules taking writers as arguments may raise exceptions).
close()
Closes the writer (for example, frees operating system resources devoted to this writer). Further operations to this writer are illegal and must be checked for by the writer.

getPos()
Tells the current position within the file. Most useful on seekable writers. Optional, in the sense that it may raise an exception if unimplemented or invalid.

endPos()
The position at the end of the file. Optional, in the sense that it may raise an exception if unimplemented or invalid.

setPos(i)
Moves to position i in the file, so future writes occur at this position. Optional, in the sense that it may raise an exception if unimplemented or invalid.

One of writeBlock, writeaBlock, writeNoBlock, or writeaNoBlock must be provided. Providing more of the optional functions increases functionality and/or efficiency of clients:

1. Absence of all of writeBlock, writeaBlock, and block means that blocking output is not possible.
2. Absence of all of writeNoBlock, writeaNoBlock, and canOutput means that non-blocking output is not possible.
3. Absence of writeNoBlock means that non-blocking output requires two system calls (using canOutput, writeBlock).
4. Absence of writeaBlock or writeaNoBlock means that extra copying will be required to write from an array.
5. Absence of writeaNoBlock, writeNoBlock, and canOutput from a writer means that nonblocking output is impossible. But the standard StreamIO modules do not support nonblocking output anyway.
6. Absence of setPos prevents random access.

Unlike readers, which can expect their getPos functions to be called frequently, writers need not implement getPos in a super-efficient manner: a system call for each getPos is acceptable. Furthermore, getPos need not be supported for writers (it may raise an exception), whereas for readers it must be implemented (even if inaccurately).

The augmentOut function takes a writer w and produces a writer in which as many as possible of writeBlock, writeaBlock, writeNoBlock, writeaNoBlock are provided, by synthesizing these from the operations of w.

Exceptions
The PrimIO functions (component fields of readers and writers) may raise the following exceptions:

Subscript for any function taking the \{data, first, nelems\} type, if first and nelems imply an out-of-bounds reference to data.

SysErr for any function that performs a system call.

ClosedStream for attempted operations on closed readers or writers.

• Other exceptions as needed for special purposes (unconventional readers and writers).

Readers and writers should not, in general, raise the Io exception.
4 PrimIO

The functor PrimIO builds standard instances of the PRIM_IO signature.

functor PrimIO(structure A : MONO_ARRAY
structure V : MONO_VECTOR
sharing type A.elem=V.elem
sharing type A.vector=V.vector
val someElem : A.elem
type pos) : PRIM_IO =

struct . . . end

The only nontrivial parts of the PrimIO functor are the implementations of the functions augmentIn, and augmentOut, which simulate one kind of reader (or writer) functionality in terms of other kinds. For example:

fun augmentIn (r as Rd r') =
  let fun readToRead reada i =
    let val a = A.array(i,someElem)
    val i' = reada{data=a,first=0,nelems=i};
    in A.extract(a,0,i')
  end
  fun stripOption (SOME x) = x
  val readBlock' =
  case r
  of Rd{readBlock=SOME f,...} => SOME f
    | Rd{readBlock=SOME f,...} => SOME(readToRead f)
    | Rd{readNoBlock=SOME f[block=SOME b,...]} =>
      SOME(fn i => (b(); stripOption(f i)))
    | Rd{readNoBlock=SOME f[block=SOME b,...]} =>
      SOME(fn i => (b(); stripOption(readToRead f i)))
    | _ => NONE
  in Rd{block= #block r',... readBlock=readBlock',...}
end

5 STREAM_IO

The Stream I/O interface provides buffered reading and writing to input and output streams.

Input streams are treated in the lazy functional style: that is, input from a stream r yields a finite vector of elements, plus a new stream r'. Input from r again will yield the same elements; to advance within the stream in the usual way it is necessary to do further input from r'. This interface allows arbitrary lookahead to be done very cleanly, which should be useful both for ad hoc lexical analysis and for table-driven, regular-expression-based lexing.

Output streams are handled more conventionally, since the lazy functional style doesn't seem to make sense for output.

signature STREAM_IO =
sig
  structure PrimIO: PRIM_IO
  type elem sharing type elem = PrimIO.elem
  type vector sharing type vector = PrimIO.vector
  type pos sharing type pos = PrimIO.pos
  type instream
end
Each instream \( f \) can be viewed as a sequence of "available" elements (the buffer or sequence of buffers) and a mechanism (the reader) for obtaining more. After an operation \( (v, f') = \text{input}(f) \) it is guaranteed that \( v \) is a prefix of the available elements. In a "truncated" instream, there is no mechanism for obtaining more, so the "available" elements comprise the entire stream. In a "terminated" outstream, there is no mechanism for outputting more, so any output operations will raise the \text{Io} exception.

\textbf{PrimIO}

Every instance of STREAM\_IO is built over an instance of PRIM\_IO.

\textbf{elem}

A single element (member of a stream).

\textbf{vector}

A sequence of elements, just as in PRIM\_IO.

\( f = \text{mkInstream}(r) \)

Create a buffered stream \( f \) from a reader \( r \). (Most users will normally use \text{TextIO.openIn} instead.)

\( \text{closeIn}(f) \)

Truncate \( f \), and release operating system resources associated with the underlying file (if any).

\( g = \text{setPosition}(f, i) \)

Now \( g \) is a new instream starting from position \( i \) of \( f \). \( f \) may or may not be truncated, depending on whether the setPos request can be satisfied within the buffer. (Nondeterministic behavior? is that bad?) \textit{Not always supported.}

\( \text{getPosIn}(f) \)

Return the current position of \( f \). \textit{Not always supported.}

\( \text{endPosIn}(f) \)

Return the position at end of file of \( f \). \textit{Not always supported.}
\[(v, f') = \text{input}(f)\]

If any elements of \(f\) are available, return sequence \(v\) of one or more elements and the “remainder” \(f'\) of the stream. If \(f\) is at end of file, return the empty sequence. Otherwise read from the operating system (which may block) until one of those conditions occurs.

\[v = \text{inputAll}(f)\]

Return the vector \(v\) of all the elements of \(f\) up to end of stream. Semantically equivalent to:

\[
\begin{align*}
\text{fun inputAll}(f) &= \text{let val } (a, f') = \text{input } f \\
&\quad \text{in if size}(a) = 0 \text{ then } a \\
&\quad \text{else } a \ ^{\text{^\wedge}} \text{ inputAll } f' \\
&\text{end}
\end{align*}
\]

where \(^\wedge\) is the concatenation operator on element vectors.

\[(v, f') = \text{inputNoBlock}(f)\]

If any non-empty sequence \(v\) of \(f\) is available or can be read from the operating system without blocking, return \((\text{some}(w, f'))\) where \(w\) is any non-empty prefix of \(v\), and \(f'\) is the “rest” of the stream. Otherwise return \(\text{none}\).

\[(c, f') = \text{input1}(f)\]

If at least one element \(e\) of \(f\) is available, return \((\text{some}(e), f')\). If \(f\) is at end of file, return the \(\text{none}\). Otherwise read from the operating system (which may block) until one of those conditions occurs. Semantically equivalent to:

\[
\begin{align*}
\text{fun input1}(f) &= \text{let val } (v, f') = \text{input } f \\
&\quad \text{in if size}(v) = 0 \text{ then NONE else SOME(sub}(v, 0)), \\
&\quad \text{f'}) \\
&\text{end}
\end{align*}
\]

\[(v, f') = \text{inputN}(f, n)\]

If at least \(n\) elements remain before end of stream, return the first \(n\) elements. Otherwise, return the (possibly empty) sequence of elements remaining before end of stream. Blocks if necessary. (This was the behavior of the \text{input} function in the 1989 \emph{Definition of Standard ML}.) Semantically equivalent to:

\[
\begin{align*}
\text{fun inputN}(f, 0) &= (\text{empty}, f) \\
| \text{inputN}(f, n) &= \text{let val } (x, f'') = \text{input1 } f \\
&\quad \text{val } (s, f''') = \text{inputN}(f, n-1) \\
&\quad \text{in } (x ^{\text{^\wedge}} s, f''') \\
&\text{end}
\end{align*}
\]

\text{endOfStream}(f)

False if any characters are available in \(f\); true if \(f\) is at end of stream. Otherwise reads (perhaps blocking) until one of these conditions occurs. Exactly equivalent to \((\text{size}(\text{input } f) = 0)\).

\text{getReader}(f)

Extract the underlying \texttt{reader} from \(f\). Truncates \(f\). Careful users should probably do something like

\[
\text{let val } r = \text{getReader } f \\
\text{val } v = \text{inputAll } f \\
\text{in } \ldots \\
\text{end}
\]

so as to obtain the elements \(v\) already in the buffer before doing anything with \(r\).
Create a buffered outstream \( f \) from a writer \( w \). In \( w \), writeBlock, writeBlock, and block must not all be NONE or an io exception will be raised.

\[
f = \text{mkOutstream}(w, s)
\]

\( f \) is a buffered outstream from a writer \( w \). In \( w \), writeBlock, writeBlock, and block must not all be NONE or an io exception will be raised.

\[
\text{closeOut}(f)
\]
Flush \( f \)'s buffer, terminate \( f \), then close the underlying writer (releasing operating-system resources associated with it).

\[
\text{flushOut}(f)
\]
Flush \( f \)'s buffer: that is, make the underlying file reflect any previous output operations.

\[
\text{output}(f, v)
\]
Write the sequence \( v \) to \( f \); this may block until the system is prepared to accept more output. StreamIO does not provide any nonblocking output function.

\[
\text{output}(f, x)
\]
Write the element \( x \) to \( f \); may block.

\[
\text{getWriter}(f)
\]
Get the underlying writer associated with \( f \). Flashes and terminates \( f \).

\[
\text{getPosOut}(f)
\]
Give the current position of \( f \) in the underlying file. Not always supported.

\[
\text{endPosOut}(f)
\]
The position at the end of file \( f \). Not always supported.

\[
\text{setPosOut}(f, i)
\]
Set the current position of \( f \) in the underlying file to \( i \). Flush \( f \) if necessary. Not always supported.

Any prefix of the concatenation of previous writes (since the last setPos or flush) may be reflected in the underlying file.

Operations marked Not always supported may fail on some streams or in some instantiations of the STREAM.IO signature, raising io.

Rules: The following expressions are all guaranteed true, if they complete without exception.

Input is semi-deterministic: input may read any number of elements from \( f \) the “first” time, but then it is committed to its choice, and must return the same number of elements on subsequent reads from the same point.

\[
\text{let val } (a, _) = \text{input } f \\
\text{val } (b, _) = \text{input } f \\
\text{in } a = b \\
\text{end}
\]

Closing a stream just causes the not-yet-determined part of the stream to be empty:

\[
\text{let val } (a, f') = \text{input } f \\
\text{val } _ = \text{closeIn } f \\
\text{val } (b, _) = \text{input } f \\
\text{in } a = b \text{ andalso endOffStream } f' \\
\text{end (* must be true *)}
\]

Closing a terminated stream is legal and harmless:

\(
\text{(closeIn } f; \text{ closeIn } f; \text{ true)}
\)

If a stream has already been at least partly determined, then input cannot possibly block:
let val a = input f
in case inputNoBlock f
  of SOME a => a/b
  | NONE => false
end (* must be true *)

Note that a successful **inputNoBlock** does not imply that more characters remain before end-of-file, just that reading won’t block.

A freshly opened stream is still undetermined (no “read” has yet been done on the underlying reader):

```ml
let val a = TextIO.openIn name (* or mkInstream(x),
  or BinIO.openIn name *)

in close a;
  size(input a) = 0
end
```

This has the useful consequence that if one opens a stream, then extracts the underlying reader, the reader has not yet been advanced in its file.

Closing a stream guarantees that the underlying reader will never again be accessed; so input can’t possibly block:

```ml
(case (close f; inputNoBlock f) of SOME _ => true | NONE => false)
```

The **endOfStream** test is equivalent to **input** returning an empty sequence:

```ml
let val (a,_) = input f  in (size(a)=0) = (endOfStream f)  end
```

**getPosIn** is accurate even if two different instreams are created from the same reader and they interleave operations. Thus, the implementation of StreamIO must make no assumption that the position at the end of one **read** operation is the same as the position at the beginning of the next.

**Exceptions** StreamIO functions may raise the **Subscript** exception, if given ill-formed array and bounds arguments by a client; or the **Io** exception. In general, when **Io** is raised as a result of a failure in a lower-level module (**PrimIO**), the underlying exception is propagated up as the **cause** component of the **Io** exception value.

This will usually be a **Subscript**, **SysErr**, or **Fail** exception, but the **StreamIO** module will rarely (perhaps never) need to inspect it.

The components of **Io** are:

- **function**
  The name of the **StreamIO** function raising the exception.

- **name**
  Should equal the **name** component of the reader or writer.

- **cause**
  The underlying exception raised by the reader or writer, or detected by **StreamIO**. Some of the standard causes are:

  - **OS.SysErr** if an actual system call was done and failed;
  - **General.BlockingNotSupported** for **output**, **output1**, **flushOut**, if the underlying writer does not support blocking writes; or for **input**, **inputN**, **input1**, **inputAll** if the underlying reader does not support blocking reads.
  - **General.NonBlockingNotSupported** for **inputNoBlock**.
  - **General.TerminatedStream** for **setPosIn** on a terminated stream.
  - **General.ClosedStream** for any output operation on a closed file. This exception is actually raised by the reader or writer. (Input operations on closed streams will generally raise Terminated.)
The *cause* field of *Io* is not limited to these particular exceptions. Users who create their own readers or writers may raise any exception they like, which will be reported as the *cause* field of the resulting *Io* exception.

**Unbuffered I/O** That is, if `chunkSize=1` in the underlying reader, then *input* operations must be unbuffered:

```latex
let val f = mkInstream(reader)  
val (a,f') = input(f,n)  
val PrimIO.Rd(chunkSize,...)=getInstream f  
in chunkSize>1 orelse endOfStream f'  
end
```

Though *input* may perform a *read*(*k*) operation on the reader (for *k* ≥ 1), it must immediately return all the elements it receives. However, this does not hold for partly determined instreams:

```latex
let val f = mkInstream(reader)  
val _ = doInputOperationsOn(f)  
val (a,f') = input(f,n)  
val PrimIO.Rd(chunkSize,...)=getInstream f  
in chunkSize>1 orelse endOfStream f' (* could be false*)  
end
```

because in this case, the stream *f* may have accumulated a history of several responses, and *input* is required to repeat them one at a time.

Similarly, output operations are unbuffered if `chunkSize=1` in the underlying writer. Unbuffered output means that the data has been written to the underlying writer by the time *output* returns.

**Don't bother the reader** *input* must be done without any operation on the underlying reader, whenever it is possible to do so by using elements from the buffer. This is necessary so that repeated calls to *endOfFile* will not make repeated system calls.

This rule could be formalized by defining a “monitor:"

```latex
val monitor: reader -> {rd: reader,  
charsRead: int ref,  
opCount: int ref}
```

and making statements such as:

```latex
let val {rd,charsRead,opCount} = monitor(reader)  
val f = mkInstream(rd)  
val (f',nElems) = doThingsCountingElements(f)  
val p1 = getPosIn f'  
val c1 = !charsRead  
val ops = !opCount  
val _ = input f'  
in not ((nElems < c1) andalso (!opCount > ops))  
end
```

but perhaps this level of detail is unnecessary.

**Multiple end-of-file** In Unix, and perhaps in other operating systems, there is no notion of “end of stream.” Instead, by convention a *read* system call that returns zero bytes is interpreted to mean end of stream. However, the next read to that stream could return more bytes. This situation would arise if, for example,

- the user hits cntl-D on an interactive tty stream, and then types more characters;
• input reaches the end of a disk file, but then some other process appends more bytes to the file.

Consequently, the following is not guaranteed to be true:

```ml
let val z = endOfStream f
val (a,f') = input f
val x = endOfStream f'
in x = z (* not necessarily true! *)
end
```

The “don't bother the reader” rule, combined with the definition of `endOfStream`, guarantees that `endOfStream(f) = endOfStream(f')`.

Implementors should beware that an empty buffer sometimes means end of stream, and sometimes not; I found an extra boolean variable necessary to keep track.

# 6 StreamIO

The functor `StreamIO` layers a buffering system on a primitive IO module:

```ml
functor StreamIO(structure PrimIO : PRIM_IO
structure Vec: MONO_VECTOR
structure Arr: MONO_ARRAY
val someElem : PrimIO.elem
val posLess : PrimIO.pos * PrimIO.pos -> bool
val posDiff : ((lo: PrimIO.pos, hi: PrimIO.pos) -> int) option
sharing type PrimIO.elem = Arr.elem = Vec.elem
sharing type PrimIO.vector=Arr.vector=Vec.vector
sharing type PrimIO.array=Arr.array
) : STREAM_IO = ...
```

The `Vec` and `Arr` structures provide Vector and Array operations for manipulating the vectors and arrays used in PrimIO and StreamIO. The element `someElem` is used to initialize buffer arrays; any element will do.

The types `instream` and `outstream` in the result of the `StreamIO` functor must be abstract.

If `flushOut` finds that it can do only a partial write (i.e., `writeBlock` or a similar function returns a "number of elements written" less than its "nelems" argument) then `flushOut` must adjust its buffer for the items written and then try again. If the first or any successive write attempt returns zero elements written (or raises an exception) then `flushOut` raises an `Io` exception.

If an exception occurs during any `StreamIO` operation, then `StreamIO` must, of course, leave itself in a consistent state, without losing or duplicating data.

In some ML systems, a user interrupt aborts execution and returns control to a top-level prompt, without raising any exception that the current execution can handle. It may be the case that some information must be lost or duplicated. Data (input or output) must never be duplicated, but may be lost. This can be accomplished without `StreamIO` doing any explicit masking of interrupts or locking. On output, the internal state (saying how much has been written should be updated before doing the `write` operation; on input, the `read` should be done before updating the count of valid characters in the buffer.

`StreamIO` does not need `PrimIO.pos` to be any kind of integer, but it must be a total ordering with a total and irreflexive comparison operator `posLess` supplied, and the `PrimIO` read operations must semimonotonically increase the position values.

Implementation notes:

The previous section gives the specification of `StreamIO` behavior.

With buffered reading, a `getPosIn` operation on the `instream` may be done in the middle of a buffer. Calculating this requires knowing the position of the beginning of the buffer, and using `findPos`. But this
means that the StreamIO system must do a getPos just before reading each new buffer, and remember that position.

Here are some suggestions for efficient performance:

- Operations on the underlying readers and writers (readBlock, etc.) are expected to be expensive (involving a system call, with context switch).

- Small input operations can be done from a buffer; the readBlock or readNoBlock operation of the underlying reader can replenish the buffer when necessary.

- Each reader may provide only a subset of readBlock, readNoBlock, block, canInput, etc. An augmented reader that provides more operations that can be constructed using PrimIO.augmentIn; but it may be more efficient to use the functions directly provided by the reader, instead of relying on the constructed ones. The same applies to augmented writers.

- Keep the position of the beginning of the buffer on a multiple-of-chunkSize boundary, and do read or write operations with a multiple-of-chunkSize number of elements.

- For very large inputAll or inputN operations, it is (somewhat) inefficient to read one chunkSize at a time and then concatenate all the results together. Instead, it is good to try to do the read all in one large system call; that is, readBlock(n). However, in a typical implementation of readBlock this requires pre-allocating a vector of size n. If the user does inputAll() or inputN(maxint), either the size of the vector is not known a priori or the allocation of a much-too-large buffer is wasteful. Therefore, for large input operations, query the size of the reader using endPos, subtract the current position, and try to read that much. But one should also keep things rounded to the nearest chunkSize.

- Subtracting the current position is difficult (!) if pos is an abstract type. The optional function posDiff is provided to compute (even approximately) the distance (in elements) between two positions. A slight overestimate in the computation is better than a slight underestimate.

- The use of endPos to try to do (large) read operations of just the right size will be inaccurate on translated readers. But this inaccuracy can be tolerated: if the translation is anything close to 1–1, endPos will still provide a very good hint about the order-of-magnitude size of the file.

- Similar suggestions apply to very large output operations. Small outputs go through a buffer; the buffer is written with writeaBlock. Very large outputs can be written directly from the argument string using writeBlock.

- A lazy functional instream can (should) be implemented as a sequence of immutable (vector) buffers, each with a mutable ref to the next “thing,” which is either another buffer, the underlying reader, or an indication that the stream has been truncated.

- The input function should return the largest sequence that is most convenient; usually this means “the remaining contents of the current buffer.”

- To support non-blocking input, use readNoBlock if it exists, otherwise do canInput followed (if appropriate) by readBlock.

- To support blocking input, use readBlock if it exists, otherwise do readNoBlock followed (if would block) by block and then another readNoBlock.

- To support lazy functional streams, readaBlock and readaNoBlock are not useful; they are included only for completeness.

- SetPosIn, if setPos-ing forward, might choose to follow the buffer sequence, and can perhaps satisfy the setPos request without any underlying reader operation.

- GetPosIn, in some implementations, can tell the position without a system call, if it knows the position of the beginning of the buffer and the current position within the buffer.
writeABlock should, if necessary, be synthesized from writeBlock, and vice versa. Similarly for writeNoBlock and writeNoBlock; readABlock and readNoBlock; readABlock and readBlock.

7 IO functor

The precise definition of "conventional" streams (IO signature) is in terms of "lazy functional" streams (STREAM_IO). The functor IO is provided:

functor IO(structure S : STREAM_IO) : IO = ...

The structures BinIO and TextIO are (presumably) built using separate applications of this functor (though TextIO is then enhanced with stdIn, etc.), but users may apply the StreamIO and IO functors to make streams data types other than char and byte.

The semantics of IO are simple enough that it is sufficient to give a reference implementation.

functor IO(structure S : STREAM_IO) : IO =
let abstraction I : IO =
  struct
    structure StreamIO = S
    type instream = S.instream ref
    type outstream = S.outstream ref
    type elem = S.elem
    type vector = S.vector
    type pos = S.pos
    val mkInstream = ref
    val getInstream = !
    val setInstream = op :=
    val mkOutstream = ref
    val getOutstream = !
    val setOutstream = op :=
    fun endOf f = if S.endOfStream f then f else endOf(#2(S.input f))
    fun closeIn(r as ref f) = (S.closeIn f; r := endOf f)
    fun setPosIn(r as ref f, i) = r := S.setPosIn(f, i)
    val getPosIn = S.getPosIn o !
    val endPosIn = S.endPosIn o !
    fun inputN(r as ref f, n) = let val (v,f') = S.inputN(f,n) in r := f'; v end
    fun input(r as ref f) = let val (v,f') = S.input f in r := f'; v end
    fun input1(r as ref f) = let val (v,f') = S.input1 f in r := f'; v end
    fun inputNoBlock(r as ref f) =
      case S.inputNoBlock f of SOME(v,f') => (r := f'; SOME v)
    | NONE => NONE
    fun inputAll(r as ref f) = let val v = S.inputAll f in r := endOf f; v end
    val endOfStream = S.endOfStream o !
    fun lookahead(ref f) = #1(S.input1 f)
    val closeOut = S.closeOut o !
    fun output(ref f, v) = S.output(f,v)
    fun output1(ref f, x) = S.output1(f,x)
    val getPosOut = S.getPosOut o !
    fun setPosOut(ref f, i) = S.setPosOut(f, i)
    val endPosOut = S.endPosOut o !
    val flushOut = S.flushOut o !
    ...
  end
end
Note that the **instream** and **outstream** types are abstract. Some consequences of this definition: The `endOfStream` semantics are

```pascal
fun endOfStream (f as ref ff) = StreamIO.endOfStream ff
```

This implies

```pascal
let val x = endOfStream f
val y = endOfStream f
in x=y (* guaranteed true *)
```

Furthermore, second call to `endOfStream` is guaranteed not to do any system call; this is a consequence of the "Don't bother the reader" semantics of `StreamIO.input`.

However, reading past end of stream is possible via `input`; the semantics may be straightforwardly derived from the semantics of `StreamIO.input`.

The output operations (which were not lazy functional to begin with) are even more similar between STREAM.IO and IO. The only purpose of the extra `ref` in IO is to allow "output redirection."

### 8 Application Notes

#### 8.1 Random access reading/writing to the same stream

Instreams are instreams, outstreams are outstreams, and ne'er the twain shall meet. At least, not face to face. However, competent users can construct many things from the layered functors.

Here's an example: reading and writing to the same random-access file without re-opening it.

1. Open the file for reading, and for writing; extract the underlying reader and writer, discarding the buffering layer.

   ```pascal
   val reader = TextIO.StreamIO.getReader
               (TextIO.getInstream(TextIO.openIn name))
   val writer = TextIO.StreamIO.getWriter
               (TextIO.getOutstream(TextIO.openOut name))
   ```

2. Do some buffered writes; then discard the buffering layer.

   ```pascal
   let val out = TextIO.mkOutstream(TextIO.StreamIO.mkOutstream(writer))
   in TextIO.setPosOut(out,somePos);
       output(out,"Hello ");
       output(out,"World\n");
       flushOut out
   end
   ```

3. Do some buffered reads; then discard the buffering layer.

   ```pascal
   let val inf = TextIO.mkInstream(TextIO.StreamIO.mkInstream(reader))
   in TextIO.setPosIn(inf,anotherPos);
       input inf;
       input inf
   end
   ```

4. And so on. It's cheap and easy to do `mkInstream` whenever switching between reading and writing.
8.2 Other reader/writer devices

The functions `TextIO.openIn` and `TextIO.openOut` provide system-default ways to create streams (whose underlying readers and writers can be extracted), from "file names."

SML implementations are likely to provide other ways to create readers and writers. For example,

```sml
structure Socket :
  sig 
    type socketName
  structure P = TextIO.StreamIO.PrimIO
  val openSocketTextReader : socketName -> P.reader
  val openBidirectionalSocket : socketName ->
      P.reader * P.writer
...
end
```

Then the user could buffer these readers by using `mkInstream`.

Alternatively, a `Socket` interface could provide the high-level `instream`:

```sml
structure Socket :
  sig 
    type socketName
  val openSocketTextIn : socketName -> TextIO.instream
  val openBidirectionalSocket : socketName ->
      TextIO.instream * TextIO.outstream
...
end
```

and the user could extract the reader by using `getInstream` and `getReader`.

8.3 String readers/writers

A useful kind of reader/writer is an internal text queue, not using any devices at all:

```sml
local
  fun primPipe : TextIO.StreamIO.PrimIO.reader *
      TextIO.StreamIO.PrimIO.writer =
...

in
  fun pipe : instream * outstream =
      (* layer mkInstream and mkOutstream on
       components of primPipe() *)

end
```

It would be natural to provide such functions in a library.

Here's an even simpler example:

```sml
fun stringReader : TextIO.StreamIO.PrimIO.reader =
    let val pos = ref 0
    fun read n = let val p = !pos
                val m = min(n, size source - p)
                in pos := p+m; substring(source,p,m)
    end

Rd{readNoBlock = SOME(fn n => SOME(read n)),
    readaNoBlock = NONE,
    readBlock = SOME(read),
    readaBlock= NONE,
    block = SOME(fn()=>()),
    canInput = SOME(fn()=>true),
```

22
name="<string>", chunkSize=size source, close=fn()=>(),
getPos=fn()=FilePosInt.fromDefault(!pos),
findPos=fn({data,first,nelems},p)=p+nelems,
setPos=((fn k => if 0<=k andalso k <= size source then pos:=k
  else raise Fail "position out of bounds")
  o FilePosInt.toDefault),
endPos=(fn()=FilePosInt.fromDefault(size source))
end

val openString : string → instream =
  TextIO.mkInstream o TextIO.StreamIO.mkInstream o stringReader

8.4 Translated readers

Sometimes one wants to apply a translation function to a stream. For example, one might want to translate
CR-LF to LF on input, or translated escape-coded ASCII into Unicode. I shall discuss translated input
streams (readers) here, but the same ideas apply to translated output streams (writers).

Since anyone is allowed to counterfeit a reader, it is easy to write a translation function on readers:

fun translate1 (source : TextIO.PrimIO.reader) : TextIO.PrimIO.reader or
fun translate2 (source : BinIO.PrimIO.reader) : TextIO.PrimIO.reader

Here's an example:

fun remove_CR(rd as TextIO.StreamIO.PrimIO.Rd rd) :
  TextIO.StreamIO.PrimIO.reader =
  let fun charCR(#)"\013") = ""
    | charCR c = implode c
  fun stringCR s = concat(mapChar charCR (s,0,size s))
  fun option f NONE = NONE
    | option f (SOME x) = SOME(f x)
  fun retranslate(_,0,pos) = pos
    | retranslate(read,nelems,pos) =
      let val s = read nelems
        val len = size s
        fun loop(i,n,p) = if i=s then retranslate(read,n,p)
          else if n=0 then p
          else if CharVector.sub(s,i)="\013"
            then loop(i+1,n,p)
            else loop(i+1,n-1,p)
      in loop(0,nelems,pos)
    end
  in TextIO.StreamIO.PrimIO.Rd{
    readNoBlock = option (fn get => option stringCR o get)
      (#readNoBlock rd,)
    readaNoBlock = (* etc. *),
    readBlock = option (fn get => stringCR o get) (#readBlock rd),
    readaBlock = (* etc. *),
    block = #block rd,
    canInput = #canInput rd,
    name = #name rd,
    chunkSize = #chunkSize rd,
  }

close= #close rd,
setPos=#setPos rd,
endPos=#endPos rd,
getPos=#getPos rd,

findPos=
case (TextIO.StreamIO.PrimeIO.augmentIn rd0)
of TextIO.StreamIO.PrimeIO.Rd{readBlock=SOME readb,...} =>
  fn {{data,first,nelems},pos} =>
    let val p0 = #getPos rd ()
      val p1 = #setPos rd pos;
    retranslate(readb,nelems,pos))
in #setPos rd p0; p1
end
| _ => raise Fail "Cannot findPos"
end

Note that the positions in this translated reader (and thus in the translated stream) do not correspond
1-1 to positions in the underlying reader. Thus, findPos must be implemented. A good, simple solution is
to avoid random access on translated streams:

findPos = fn _ => raise Fail "Cannot findPos"

But here we have chosen to provide findPos whenever possible. Because the translation is not invertible
we don't know where the CR characters might have been, findPos must re-read the original stream.

Users who need to do random access on translated streams might also use a solution similar to the one in section 8.1: do setPos on the underlying, untranslated reader. Then, after each setPos, apply afresh the
translation function (such as remove_CR and then apply a new buffer (via mkInstream).

8.5 Abstract positions

In applications where one wants seekable, translated readers with “moded escapes” it is difficult represent
positions as integers. This will happen if escape characters semi-permanently change the translation state
of a stream, rather than affecting just the next character.

In such a case, one might want to have an abstract data type position, with a total ordering but without
a mapping to integers.

One way to accomplish this is to make a new structure matching the PRIM_IO signature:

abstraction MyTextPrimIO : PRIM_IO =
  PrimIO(structure A = CharArray
  structure V = CharVector
  val someElem = "/\000"
  type pos = MyPosType.pos)

Now one can write translated readers that can deal with translated positions more flexibly.

The StreamIO functor can be used to create a buffered I/O system for these new readers/writers:

structure MyStreamIO =
  StreamIO(structure PrimeIO = MyPrimeIO
    val posLess = MyPosType.<
    val posDiff = NONE)

Or, posDiff=SOME(MyPosType.-) if possible.

Now MyStreamIO.instream is a different type than TextIO.StreamIO.instream, so one cannot use the
same function to operate on both kinds of instreams unless this function is in a functor parameterized by
StreamIO.

Also, it is possible to write a function to translate a MyPrimeIO.reader into an ordinary PrimeIO.reader
(but with setPos disabled):
val NoRandomAccess = Fail "Random access not supported on this stream"

fun standardize (MyPrimIO.Rd rd) =
  TextIO.StreamIO.PrimIO.Rd{
    readNoBlock = #readNoBlock rd,
    readaNoBlock = #readaNoBlock rd,
    readBlock = #readBlock rd,
    readaBlock= #readaBlock rd,
    block = #block rd,
    canInput = #canInput rd,
    name= #name rd,
    chunkSize= #chunkSize rd,
    close= #close rd,
    getPos=fn _ => 0,
    findPos=fn _ => raise NoRandomAccess,
    newPos=fn _ => raise NoRandomAccess,
    endPos=fn _ => raise NoRandomAccess}

8.6 Lexical analysis

Lexical analyzers need to process their input efficiently, and often need some amount of lookahead. Line-oriented applications need to read one line of text at a time, efficiently. Both of these applications can make effective use of lazy-stream input.

Consider the implementation of an inputLine function, that reads up to the next newline character. A naive implementation would read characters, then concatenate them:

fun inputLine (f/: TextIO.instream) =
  let fun loop () = case input1 f
    of SOME("\n") => "\n"
    | SOME c => c :: loop()
    | NONE => nil
  in implode (loop())
end

Now, we may wish to avoid all the list construction and implode call. Thus:

fun inputLine (f/: TextIO.instream) =
  let val g0 = TextIO.getInstream f
  in TextIO.inputN(loop(0,g0))
end

This has the effect of looking through the input buffer for a newline character, then extracting just the right-length string from the input buffer; but it’s all done abstractly.

There are no list constructions, and only one string copy: the extract implied by the inputN call. On the other hand, there is a function call for each character; I do not see this as a problem. We expect ML programs (or, in fact programs in any language) to implement abstract data types via a function-call interface; if this becomes a source of inefficiency, perhaps the solution is for compilers to implement cheaper function calls.

A very similar approach works for lexical analyzers which do more general (perhaps multi-character) lookahead: First scan the lazy stream to determine the length of the token, then use inputN to extract it and advance the stream.

InputLine is provided as a standard function of TextIO, but this implementation is explained to illustrate how variations on it can be constructed.
